Abstract

This paper suggests a way to think about human well-being and psychological health. It distinguishes between mental stocks and flows. Central to the analysis is a concept we refer to as hedonic capital. This can be thought of as a level of emotional coping resources, or as the underlying stock to which the economist's idea of a flow of utility corresponds. The model replicates the patterns found in the recent empirical psychology and economics literature: there is an approximately stable level of mental well-being and an automatic tendency to adapt back towards that level. Conventional economic theory does not fit these facts.

Acknowledgments: We have received valuable suggestions from participants in an IZA Behavioural Economics Conference in Bonn, and from George Ainslie, Andrew Clark, Amanda Goodall, Danny Kahneman, Satoshi Kanazawa, James Konow, Yaojun Li, Luis Rayo, Claudia Senik, Alois Stutzer, and Stephen Wright.

Keywords: Adaptation; well-being; evolution; happiness; habituation.

JEL codes: D1, I1, I3.

Hedonic Capital and the Foundations of Mental Health

1. Introduction

This paper is about human coping and the foundations of psychological health. Although it is theoretical, the aim is to help the work of applied economists and to provide empirical predictions. The paper builds on new research, by economists such as Carol Graham (2008) and psychologists such as Ann Masten (2007), at the border between mental and physical health.

Human beings are deeply adaptive, self-repairing organisms. They recover psychologically from bad life events and adapt to good ones. Despite what conventional economic theory predicts, movements in mental well-being thus tend to exhibit a form of mean-reversion. This is the phenomenon¹ of habituation or hedonic adaptation. By contrast, standard economics is silent on the possibility of psychological recovery, and assumes that individuals have a utility function where influences such as income, disability, job promotion and bereavement have lasting, once-and-for-all effects.

How can we make conceptual sense of the fact that humans spring back indomitably from adversity? Resilience as a concept is widely used in the psychology and psychiatry literatures. Masten (2007) provides a review. She defines resilience as “the capacity of dynamic systems to withstand or recover from significant disturbances” and notes that it is closely related to adaptation. Yet the concept of resilience has no role, or counterpart, in the subject of economics.

An early exposition was provided by Duesenberry (1949). There is a related literature on other kinds of comparisons. Recent research includes Frank and Sunstein (2001), Burchardt (2001), Senik (2004), Hopkins and Kornienko (2004), Luttmer (2005), and Alpinar, Carlsson and Johansson-Stenman (2005). Earlier work is

2. Adaptation

Economists have recently applied microeconomic time-series techniques to look at the path of well-being over time, and the resulting response functions provide an illustration of adaptation. For example Graph 1, taken from Clark et al (2008) shows, using data from the German GSOEP data set, the time path of the well-being of females who were widowed at time 0.

Graph 1: Response of well-being for females who were widowed at time 0

The striking thing is that after 2 years the well-being of these individuals is statistically indistinguishable from its level before they were widowed. Indeed, Clark et al (2008) cannot reject the hypothesis of complete adaptation for five out of the six life events they consider. One theoretical explanation for this uses an endogenous reference level (see Frederick and Loewenstein 1999). However, while such models give an account of adaptation, they are intrinsically ad hoc, and are silent on which factors affect the steady state level of well-being, and which will influence the speed of an individual's adjustment back towards the steady state.

Adaptive behavior creates difficulties for economic theory. Economists are familiar with the idea that the marginal utility from something declines as it is consumed more heavily. They are unused, however, to the notion that the sheer passing of time might

discussed in, for example, Easterlin (1974), Layard (1980), Frank (1985), Babcock, Wang and

alter people's utility. In contrast to its centrality in psychology textbooks, almost no attention is paid to adaptation in current economics textbooks. This attitude among economists is probably partly because most are unaware of the accumulated evidence in applied-psychology journals. But it is partly deeper. It is because economists find unsatisfying the notion that, for unspecified reasons, human beings have a reference level that depends on current experience. In the adaptation literature, the presumption has been that happiness is given by a utility function $u = u(x - x^*)$, where x might be a variable like income or health, and x^* is some comparison or past reference level that automatically follows the actual level of x . The gap $x - x^*$ responds endogenously -- and in this way better income or health can slowly cease to give extra utility. Such a model of adaptive behavior, many economic theorists would argue, is uninteresting. First, it does not go beyond a restating of the observation to be understood. Second, it gives no account of the richness of individual behavior in response to shocks.

This paper suggests a different way to think about adaptation. It constructs a framework that generates the observed mean-reversion of well-being. The model achieves this by using methodological principles that are familiar to economists and without invoking an endogenous reference level. As in the innovative work of Ng (1995, 1997) and Robson (2001), we view behavior as moulded by biology and nature. More broadly, our work falls within an emerging area of research at the border between the disciplines of psychology and economics (see, for example, Kahneman, Wakker and Sarin 1997 and Kahneman 2003). It can also be viewed as part of an emerging economics of emotions (Loewenstein 2000).

At the heart of the formal modelling is one idea: to understand well-being it is valuable to distinguish between stocks and flows. Although it seems natural to view happiness as a flow variable, there is agreement in the literature that some of the important determinants of well-being have the nature of stocks. For example, Carr (2004) writes

"people with large social support networks and stronger social bonds with members of their networks have better physical and mental health, fewer

Loewenstein (1996), and Akerlof (1997).

illnesses and less depression, recover more rapidly from physical illness and psychological problems, and have a lower risk of death."

We propose a slightly unusual concept, hedonic capital. Later sections denote this by the symbol k . We view k as the stock of coping resources available to an individual. When negative utility shocks hit individuals, they draw upon their k . We leave unspecified its exact empirical foundations. Significant social relationships with friends and colleagues may form one component of hedonic capital; our definition could also include health (some stock aspects of which are discussed by Grossman (1972, 1999)), self-esteem, status, and meaningful work. For some people, religious faith may also play a part. These things are stocks in that they rely on past inputs and are carried across time periods.

Hedonic capital is to be thought of as the psychological equivalent to the physical capital used by firms. Just as machines produce output, hedonic capital produces a flow of hedonic resources which might be termed hedonic energy. We posit that this energy can be used either (i) to generate well-being today or (ii) to invest in hedonic capital to produce well-being in the future. Hedonic capital ties together the present and the future.

A machine that makes baked-bean cans depreciates as time passes. So, in our model, does hedonic capital. To keep the level of hedonic capital constant, human beings have to invest some of their mental resources in order to maintain their stock of hedonic capital.

In order to provide a formal description of such a psychological structure, the paper modifies analytical methods that are familiar from some other, very different, parts of social science, including inter-temporal optimization theory and the Ramsey model of aggregate economic growth. The novelty of the paper is not in its mathematics.

We explore how evolution might rationally 'design' an individual to respond adaptively to life events. The focus is on the limiting outcome of evolution, namely, the individual decision rules that are optimal from an evolutionary standpoint. The paper shows that an individual so designed would:

- use hedonic capital to smooth² the response of well-being to life events
- exhibit a steady-state level of well-being
- display adaptive behavior in response to shocks to permanent changes in the stock of hedonic capital.

The formal analysis also suggests, first, that the lower is the level of hedonic capital the more volatile is an individual's well-being level and, second, that those with low hedonic capital find it more difficult to recover from negative events.

The paper takes the modelling task to be to understand how human beings have come to be hedonic adapters. It does not assume that a particular man or woman chooses to adapt. For the person, adaptation is instinctive. Nature is the rational decision-maker and has chosen it for human beings.

In the model developed below, happiness can be thought of as the return on hedonic capital. This interpretation is usefully evocative. Nevertheless, such an interpretation needs to be treated cautiously. A more accurate statement, which is explained with the later algebra, is that some of the return on hedonic capital will be taken in the form of current happiness while the remainder is invested to produce well-being in later periods.

We show that:

1. The evolutionary process results in individuals who
 - a. Exhibit a steady state level of well-being (a 'set-point' in the terminology of Diener et al, 1999)
 - b. Display adaptive behaviour in response to life-events ("shocks" in our model)
2. The model predicts that the level of hedonic capital will have implications for an individual's psychological resilience:

² The smoothing in our framework is not simply the equating of marginal utilities across time.

- a. High levels of hedonic capital imply high psychological resilience i.e. low volatility of well-being;
- b. After a negative shock to the level of hedonic capital, individuals will substitute towards activities which rebuild their hedonic capital
- c. Income buffers well-being, and will do so more effectively against negative shocks than against positive ones.

3. Previous Work

Although it is not easy to explain why there is such a divide over adaptation between economists and psychologists, Oswald and Powdthavee (2008) suggest two possible reasons. First, the early empirical evidence was viewed by economists as debatable. One of the literature's most-quoted papers, for instance, is Brickman et al (1978). It is sometimes claimed in the literature that these authors prove that lottery winners are no happier than non-winners and paraplegics are as happy as able-bodied individuals. On closer inspection, Brickman et al (1978) actually report data in which disabled people do have lower life-satisfaction scores than the able-bodied, and this difference, when compared to a control group, is statistically significant at conventional levels. Moreover, lottery winners do have higher life-satisfaction scores than the controls, although the null hypothesis of no difference cannot be rejected at the 5% level. Second, one part of the psychology literature proposes the so-called 'set point hypothesis', which is the idea that people adapt completely to life shocks. Rightly or wrongly, economists view this position -- that utility effectively cannot be altered by outside events -- as sufficiently implausible that they have been loathe to give credence even to the idea of partial adaptation.

The paper by Frederick and Loewenstein (1999) is an introduction to hedonic adaptation. Another term used in the literature is 'affective adaptation', which, following Wilson and Gilbert's (2005) definition, is where affective responses weaken after one or more exposures to a stimulus. A valuable discussion, with examples, is given in Lucas et al (2003). Earlier evidence is discussed in Argyle (2001) and Diener et al (1999). Easterlin (2003, 2005a, b) argues that adaptation is generally incomplete, namely, that people do not merely automatically bounce back to a baseline level of happiness. Clark and Oswald (1994) find some evidence of partial

adaptation by the long-term unemployed. Adaptation is also discussed in the overviews by Oswald (1997), Diener et al (1999), Frey and Stutzer (2002a, b), Van Praag and Ferrer-I-Carbonell (2004) and Layard (2005).

A recent paper by Di Tella, Haisken and MacCulloch (2005) has provided more evidence. Using individual panel data on 8000 people living in Germany from 1984 to 2000, the authors estimate the size of the effect on happiness of adaptation to income and to status. They cannot reject the null hypothesis that people adapt totally to income after four years. By comparison, significant status effects remain after this time. In the short-run (the current year), a one standard deviation increase in status is associated with a similar increase in happiness to an increase of 50% of a standard deviation in income. In the long run (the past four years), a one standard deviation increase in status has a similar effect to an increase of more than 300% of a standard deviation in income.

In important theoretical contributions, Rayo and Becker (2007) and Wilson and Gilbert (2005) consider why and how human beings adapt. The first of these, by economists, likens hedonic adaptation to the ability of the eye to adjust -- for reasons of self-preservation -- to changes in the amount of light. Although very different from our approach, Rayo and Becker set out a mathematical model of how Nature might, in the underlying spirit of Robson (2002), have designed human beings' emotional responses to behave a similar way. Rayo and Becker see happiness as a kind of innately adaptive measuring rod. The second paper, by psychologists, thinks of individuals as learning to change what they actually attend to and how they react. Wilson and Gilbert suggest that hedonic adaptation is not merely the adaptation that is conventionally found in, for instance, an animal's sensory or motor systems. The authors argue that affective habituation is provoked by something else. It stems, instead, from the need and ability that humans have to make sense of the stimuli around them. Wilson and Gilbert lay out an AREA model -- attend; react; explain; adapt -- to explain habituation.

Further evidence is offered by Riis et al (2005). These authors report remarkable evidence consistent with the phenomenon of adaptation. Using an ecological momentary-assessment measure of mood, the authors find that, despite their

apparently impaired lives, hemodialysis patients are no less happy than healthy people. The authors suggest that patients in the sample have largely adapted to their condition; they show that, in a forecasting task, healthy people fail to anticipate this bounce-back in well-being. Affective forecasting is known to be imperfect (Gilbert et al 1998, 2002; Ubel et al 2005). Other investigators, such as Clark (1999), Clark et al (2004), Stutzer (2004) and Layard (2005), have begun to accumulate evidence and to consider the economic implications of how people adapt. Kahneman and Sugden (2005) discuss the policy implications of allowing for adaptation in experienced utility. Di Tella, MacCulloch and Oswald (2001, 2003) study adaptation of national happiness to movements in real income. By estimating dynamic equations, they find evidence that the well-being consequences of shocks to gross domestic product eventually wear off. They suggest a way to use difference equations to solve out for a steady-state level of habituation. Conceptually, the adaptation literature might be seen as related to new research on well-being and preferences such as Frey and Meier (2004) and Frijters et al (2004).

Three building blocks lie behind the paper's proposed framework. One is the distinction between stocks and flows; a second is the concept of a production function for happiness; a third is the notion of investment in hedonic capital. Although unfamiliar to economists, antecedents of each can be found in the psychological literature.

Headey and Wearing (1991) point to the difference between stocks and flows -- with stocks arising, in their view, from "stable personality characteristics" and flows from "events". The authors postulate a link between higher levels of a stock and higher levels of a person's well-being. Headey and Wearing also discuss the need for a dynamic equilibrium model in which

"each person is regarded as having 'normal' equilibrium levels of life events and SWB, predictable on the basis of age and personality. Only when events deviate from their equilibrium levels does SWB change. Unusually favourable events enhance SWB; unusually adverse events depress it."

In this vein, a component of our model is a production function which explains how hedonic capital produces well-being. Ormel et al (1999) describe the mechanism by which well-being is generated. They use a social production function, taking the inputs to be a range of personality characteristics and life events, and the output to be well-being, and suggest, as we later do, that there are diminishing marginal return to the inputs. Ormel et al also have a concept of emotional investment: they make a distinction between activities that immediately satisfy a goal and those which increase potential for future production.

4. The Framework

This section provides a formal model of a person's psychological structure and describes how, in an uncertain world, evolution might optimally design the individual's response to emotional shocks.

Assume that a human being begins with a given level of psychological coping resources. This stock is hedonic capital³. Hedonic resources can be used in two ways. They can be taken as happiness today or invested in hedonic capital to produce greater well-being tomorrow. By assumption in our framework, an increasing and concave function captures how hedonic capital is used to produce happiness.

Let k represent hedonic capital. Define y , which might be called hedonic energy, as a flow concept that measures the output produced by hedonic capital.

Define a variable v to capture random life-events. We assume that returns to hedonic capital are diminishing, i.e. $0 < \alpha < 1$. A parameter z represents different individual types. For simplicity, the production function of hedonic energy is assumed to take a constant-elasticity form:

$$y_t = zk_t^\alpha + v_t. \quad (1)$$

³ Another name for hedonic capital would be emotional capital. The paper does not use it because this term is occasionally employed, although in a slightly different way, in the sociological literature (Reay, 2004).

The principal ideas go through in more general settings.

The flow of hedonic energy y in period t can be used by an individual in alternative ways. One is directly to produce well-being, h , this period (i.e. to make the individual happy). The other use is in the form of an investment activity, denoted now by i . Such activities involve forgoing some well-being in order to increase the stock of hedonic capital in the future.

The emotional budget equation is:

$$y_t = h_t + i_t \quad (2)$$

which is an accounting relation. Finally, investment of hedonic energy leads to an increase in the stock of k , while depreciation reduces that stock. Assume that hedonic capital depreciates at rate δ . Then its law of motion is described by the equation:

$$k_{t+1} = (1 - \delta)k_t + i_t + \omega_t \quad (3)$$

where ω is a white-noise shock. These three equations provide a compressed description of a human being's psychological structure.

We are interested in the possible existence of a set of hard-wired behavioural rules that might emerge from a Darwinian-like process. These are to be thought of as the solution to a principal-agent problem in which the principal, 'Nature', corresponds to the process of evolution. Nature shapes the characteristics of the individual.

Why should happiness -- the well-being of individual agents -- matter to evolution?

The reason is that happiness is useful as a motivation device. In terms of selfish genes, Nature wants individuals to perform with high reproductive success. Imagine, by a natural argument, that Nature equips individuals with utility functions. Hence we enjoy having a high income, being powerful, and having sex, among other things. According to such a conceptual account, the happiness induced by particular

activities is there merely for efficiency reasons. The existence of enjoyment in human life has a pay-off to Nature: we can be motivated to do things that make us reproductively successful.

The paper applies a general version of such an argument and assumes that happiness is valuable to Nature because it makes individuals value their lives enough to take care of themselves. Consider a world where that was not true. Imagine humans were routinely miserable (or merely indifferent to being alive). They would not take care when walking on mountain cliffs, chasing prey, fighting, deciding whether to fight, and so on. This would be dangerous evolutionarily; such agents would, consciously and unconsciously, routinely commit suicide too often for their genes to replicate successfully. For reproductive efficiency, Nature needs humans to be happy enough to stay away from the cliff edge.

The mathematical set-up goes fractionally further. We assume that Nature cares about agents' happiness in a concave way. Higher and higher happiness, among the agents, is less vital to Nature's purpose than the avoidance of low levels. The risk of a low breeding rate is acute at extremely low levels of happiness (the limiting case being complete disregard for safety, or suicide), so that, for efficiency reasons, Nature will put particular weight on avoiding severe unhappiness.⁴

Mental health is as important to successful reproduction as physical health. There is a wide literature on the connection between well-being and a range of variables related to the ability to leave large numbers of offspring. Lyubomirsky et al (2005) assert a causal relation between well-being and a range of positive individual characteristics. Segerstrom and Miller (2004) show that stress is associated with a suppressed

⁴ A more formal way to think about this is as Nature recognizing that the environment is unpredictable. Imagine that, say, world temperature is a random variable, t , with density $f(t)$. Agents have utility $w(a, t, n)$ which is increasing in t , where n is some happiness-supplement designed ex ante by Nature, and where a is an action that can include the outside option of suicide; suicide generates utility 0. The agent's maximum-value function is then $z(t, n)$. Temperature is out of Nature's control, but Nature knows that at some Ice-Age-like low temperature t^* the agents will find the environment on the margin of being too cold for it to be worth living. The marginal return to Nature of providing a counteracting source of extra happiness n at level t^* is then, for Nature, extremely high. But, as t rises away from the danger level of $z(\cdot)$ close to $u(0)$, that marginal return of agents' happiness to Nature quickly becomes smaller.

immune system. A review of medical and psychological evidence is in Wilson and Oswald (2005).

Given the complexity of an individual's psychic make-up (that is, the many different factors which contribute to hedonic capital), the individual has an informational advantage over the evolutionary process. Rather than specify the detailed decision rules governing each source of well-being, and each possible type of shock, the principal chooses a set of decision rules for aggregate measured well-being. Then the principal leaves the agent -- who is better informed -- to act given these background rules. Evolution thus moulds the background characteristics of human beings; individual agents make day-to-day decisions.

Nature's objective is the maximization of a concave function of individual well-being levels

$$\max_{\{h_t\}_{t=0}^{\infty}} E \sum_{i=0}^{\infty} \ln(h_{t+i}) \quad (4)$$

where E is the expectations operator. This maximization⁵ is subject to the constraints imposed by the psychological structure of the individual, described above by equations (1) to (3). The assumption of logarithmic preferences for Nature is for simplicity; it can easily be generalized.

5. Solving the Model

We can write Nature's maximization problem in standard dynamic programming language as a choice of the current level of hedonic capital, k , conditional on an optimal choice of next period's hedonic capital (denoted by a prime on k), where

$$V(k, v) = \max_{k'} \left\{ \ln \left[(1 - \delta)k + zk^{\alpha} + v - k' \right] + \beta EV(k', v') \right\} \quad (5)$$

⁵ This could be viewed as an application of Ng's (2000) argument. The choice of a unit discount factor is for simplicity. We are describing evolution's problem, not an individual's, and it is hard to be sure if the evolutionary process discounts the future. On the related issue of inter-generational relative standing, see Johansson-Stenman et al (2002).

in which the term in square brackets is the current level of happiness as a function of today's k and tomorrow's k .

The first-order condition, an Euler equation, is

$$\frac{1}{h} = \beta E r' \frac{1}{h'} \quad (6)$$

where

$$r = (1 - \delta) + \alpha z k^{\alpha-1} \quad (7)$$

At the margin, there is a choice between taking an extra unit of hedonic energy as happiness today or investing it to produce happiness tomorrow. The left-hand side of the Euler equation is, given our assumption of logarithmic utility, the marginal benefit of the extra unit of happiness in the present period. The right hand side of equation (7) is the marginal benefit of the happiness tomorrow that would be gained from investing the extra amount. If one unit is invested in hedonic capital today, it gives r units of hedonic energy tomorrow, comprising the hedonic energy produced from that unit, $\alpha z k^{\alpha-1}$ and the un-depreciated part of the unit, $1 - \delta$. To convert this from units of hedonic energy into utility terms, it is weighted by the marginal utility of happiness tomorrow.

It is useful to have a benchmark. Hence consider a steady-state with no events, so $v=0$. In such a steady-state, we can show⁶ that the level of hedonic capital is constant and given by:

$$k = \left(\frac{\alpha z}{\delta} \right)^{\frac{1}{1-\alpha}} \quad (8)$$

where this steady-state level of hedonic capital depends, of course, on the underlying parameters of the system. It is an increasing function of z , the efficiency with which hedonic capital is used. It is a decreasing function of δ , the rate at which hedonic capital depreciates.

Here the parameter z is a feature of individuals' psychological make-up⁷. The parameter plays the role of indexing idiosyncratic characteristics, and it abstracts from

⁶ In a steady state with constant well-being, equation (6) implies $\beta r = 1$. Using this in equation (7), and rearranging, then leads to (8).

the complex interaction of genetic and developmental factors which produces “happy” individuals (with high z) or unhappy ones (with low z). We do not investigate what determines z . Instead, the paper later examines how individuals’ response to emotional shocks can differ with high or low values of z .

The parameter δ is the rate at which hedonic capital depreciates. This combines features of an individual’s make-up (perhaps how good they are at sustaining relationships) with features of society. In a society with strong community attachment and low geographical mobility, hedonic capital might depreciate at a lower rate. In a fragmented and highly mobile society, it might be more difficult to maintain attachments. Then hedonic capital will decay more quickly.

Because hedonic capital depreciates, it will be optimal in this model for the individual to use some of the hedonic energy to maintain the stock of hedonic capital. So the steady-state is also characterised by a constant level of investment in hedonic capital - at a level just enough to keep the level stable and make up for depreciation. These maintenance activities might be viewed as representing the energy put into, say, keeping up friendships and relationships.

The steady-state level of hedonic capital, when combined with the production function, (1), gives a steady-state level of well-being:

$$h = zk^a - \delta k \quad (9)$$

Equation (9) conveys the paper’s first finding. The model produces a steady-state in which happiness and hedonic capital are constant. In this sense, the model’s assumptions lead to the “set-points” commonly described in the psychological literature (e.g., in Diener et al 1999).

⁷ Will the psychological structure described by equations (1) to (3) be optimal from the point of view of evolution? The concave form of the relation between happiness and offspring implies that evolution is “risk-averse”; i.e., with the same mean level of happiness, a smooth path gives more offspring than a volatile one. This will mean it will be optimal for evolution to design a smoothing mechanism such as that provided by hedonic capital. We could model this explicitly by specifying a stochastic processes for life events, then letting evolution choose the variable z , and hence the steady-state level of hedonic capital. We do not do this, and continue to take z as exogenous, mainly because we are unable to quantify the process for life events. The parameter only matters to the extent that it gives steady-state hedonic capital in relation to which life-events are “large” or “small”.

Our characterisation of the emotional steady-state can be used to throw light on a widely cited empirical observation -- the so-called Easterlin paradox. This is the finding that, while GDP in the West has increased dramatically over the last 50 years, measured well-being has remained roughly constant. See, for example, Easterlin (1974) and, on modern data, Blanchflower and Oswald (2004).

A number of points emerge. First, there is no direct relation between income and well-being in our model. Some consequences of increasing GDP, such as widely-available health-care, better education and insurance, might lead to the parameter z increasing between different generations of individuals. This would tend to increase the steady-state level of well-being with time. However, if the growth in GDP is accompanied by an increasing rate of depreciation of hedonic capital -- such as higher mobility and the breakdown of traditional communities and roles -- this could offset the increase in a . Then the net movement of well-being would be determined by the relative magnitude of the two effects.

The preceding section characterised an individual's psychological steady-state in terms of the underlying parameters of the model. We think of this psychological steady-state as being perturbed by shocks. These shocks represent events which affect the emotional state of an individual.

There are two channels, in this model, through which external events influence the individual. The first is a one-off change in the level of a person's hedonic capital (ω in equation (3)) . Unemployment, divorce and disability are in this category. The second channel is a temporary event which has no direct effect on the level of hedonic capital but requires some psychic resources (ψ in equation (1)). Such events might be a temporary illness of the individual or someone close to them. Real-world events will, of course, often be a combination of these two types, but for clarity we analyse them in isolation. The following sections describe how an individual who has been optimally hard-wired by evolution would respond. In reality, life events can often be anticipated, either because they depend partly on an individual's behavior, or because the individual can form expectations about the future, which means that well-being

changes before the event. In what follows, however, we assume for simplicity that the events are exogenous and random.

In this framework, human beings differ along various dimensions. As explained, an individual type is indexed by three parameters: δ , the rate at which hedonic capital depreciates; α , the degree of diminishing returns to hedonic capital; and z .⁸ Different values of these parameters are to be thought of as describing different types of people. The only effect of z is to change the steady-state levels of the variables. As long as shocks are small relative to the steady-state, z does not affect the model's dynamics. We choose the two remaining parameters so that the impulse responses produced by our model replicate the known data as closely as possible. Nevertheless, it is useful to bear in mind that current empirical studies do not have enough data points to make such choices completely reliable. Well-being in, say, the time-series plots of Gardner and Oswald (2006) appears to have a half-life of approximately one year (i.e. it takes a year for the level of well-being to decay to half of its value on impact). Taking the base time period to be a month, our model replicates this with $\alpha=0.5$ and $\delta=8\%$. That value for parameter δ means that 8% of an individual's hedonic capital will decay each month. In other words, without investment, roughly two-thirds of the stock of hedonic capital will have been lost after a year. This may seem high, particularly in comparison with physical capital. But it represents an extreme case: a complete lack of investment in hedonic capital would imply an absence both of interaction with other people and of meaningful activity. Solitary confinement in prison would be one extreme example.

It is necessary to specify a process for the stochastic variable which describes the path of life events. It is here assumed that shocks are random but persistent, and follow a first-order autoregressive process

$$v_t = \rho v_{t-1} + \varepsilon_t \quad (10)$$

where ρ is a number between zero and one, and ε is a white-noise shock. The value of ρ does not affect our qualitative conclusions, so for simplicity we set it to 0.5.

6. Sketching the Time Paths of Happiness h and Hedonic Capital k after Negative and Positive Shocks

What does this model predict about dynamics?

Negative shocks to life come in two forms here. Each induces adaptive behavior, although of slightly different kinds. The time paths, derived from numerical solution, are depicted in Figures 1 and 2.

Figure 1 sets out what happens in our optimization model to the trajectory of happiness -- first falling and then bouncing back upwards -- after a fall in the level of hedonic capital. In this case what is being studied is the impact of an abrupt life-event which destroys part of an individual's k , a negative innovation to ω in equation (3). Potential examples of such an event might be divorce, disability or unemployment. The Figure mimics the adaptive pattern observed in empirical research.

The shock in Figure 1 is modelled as a one unit fall in the level of hedonic capital at time $t = 0$. The baseline level of happiness, set to 1.00 for clarity, represents the steady-state. In the Figure, there is only one external influence on the individual. Everything else is determined by the individual's hard-wired decision rules.

Happiness therefore adapts. It returns asymptotically to its starting point. Step by step, the mechanics are as follows:

1. The reduction in hedonic capital means:
 - (a) the marginal return to investing in new hedonic capital increases
 - (b) the level of hedonic energy available to the individual decreases.

⁸ There are two other parameters that relate to the evolutionary process. The first, nature's discount factor, is here normalized to unity. The second, the degree of concavity of the relation between happiness and offspring, we take simply to be captured by a log function.

2. When deciding to allocate the lower level of hedonic energy between well-being and investment, the proportion devoted to investment rises. This is because of the higher marginal return.
3. So well-being falls by proportionally more than it would were investment constant, but hedonic capital increases. Current-period well-being is foregone for future well-being.
4. In the next period, hedonic capital is higher than on impact, but still below the steady-state. Thereafter, steps 1 – 3 repeat themselves, with the marginal return, and hence investment, falling, but still being above the steady-state. This continues in each period until all the variables are back at their steady-state.

How might this process be conceptualized? Life has worsened. This individual has lost part of his or her hedonic resources. As a result, the individual puts energy into building up new resources to restore the lost hedonic capital. Taking disability as an example, he or she forgoes some parts of the hedonic capital associated with physical ability. In response, hedonic resources are diverted into re-constructing the lost capital.

Not all of life's blows are permanent. As illustrated in Figure 2, it is straightforward to use the framework to study the effect of a life-event which temporarily requires some of the individual's hedonic energy, but has no long-run effects, a negative innovation to ε in equation (10). An example might be a short-run illness of someone close to the individual. After such a temporary shock, well-being will again deviate from the steady-state, but the path of well-being in Figure 2 is much smoother than the path of the shock.

Technically, Figure 2 models a one-off negative event that slowly decreases in size over time. If hedonic capital was constant in the face of the shock, the story would end here: the individual's well-being would simply follow the path of the life-event. When people have a stock of hedonic capital, however, the response of well-being, shown by the curved line in Figure 2, is different. It reacts less initially, but more in

later periods. This is a reminder of the underlying property of hedonic capital: it is optimally used to iron out part of the individual's responses to life events. In this fashion, we have the paper's third principal result. When a bad shock strikes, the individual allows the stock of hedonic capital to fall, so freeing up hedonic energy to deal with the event. When the event has died away, the individual rebuilds hedonic capital.

Because they lie behind the happiness time paths, the trajectories of hedonic capital, k , are also of interest. Figures 3 and 4 set out those for the same negative shocks as in Figures 1 and 2. Figure 3 shows that the adaptation of well-being in Figure 1 is due to k gradually returning to its steady state in Figure 3. Figure 4 shows that the smoothing of happiness in Figure 2 is the result of stocks of k being first depleted as agents draw down on their coping resources, then rebuilt.

Figures 5 and 6 are the opposite. They turn to the case of life's ups rather than downs. Now the individual becomes happier, but the burst in happiness gradually falls away, and well-being tends asymptotically back towards the steady state of 1.00. These Figures thus correspond to the obverse of the bad shocks of Figures 1 and 2. Again in Figure 5 we see adaptation to the permanent shock; and in Figure 6 smoothing of the temporary shock. Although it should be emphasised again that the underlying nature of these two shocks is different -- the former is a one-off permanent change and the latter a steadily diminishing one -- the general structure of response in happiness in Figures 5 and 6 has the same adaptive form (though the structure of Figure 6 stems from the fact that the event is temporary). Initially, happiness is running flat along the steady-state level, given by unity, 1.00. Then it lifts abruptly. After that, there is a slow 'habituation'.

Why does the change not make the individual permanently happier? Decreasing returns to hedonic capital will mean that growth in k does not bring about a large enough increase in y to sustain the depreciation implied by a permanently higher level of capital. Therefore, although investment in hedonic capital goes up after the shock, it does not increase by enough to cover the higher depreciation implied by the greater level of hedonic capital. Put intuitively, if hedonic capital increases, more hedonic resources are required to maintain the new level of hedonic capital, whereupon less is

available elsewhere. But such a shock has lasting effects on the composition of hedonic capital. After the life occurrence has died away, the long-run level of hedonic capital is the same, but its composition is different.

What happens to hedonic adaptation if there is some lower bound on hedonic capital? This is potentially important. Such a lower bound might correspond to the concept of depression. For an individual whose psychological make-up means their steady-state level of hedonic capital is well above the lower bound (represented by a high value of z or a low value of δ), and who faces only small shocks, a lower bound will be irrelevant. Only a long sequence of negative shocks would bring the individual's level of hedonic capital near to it. Nevertheless, consider someone who has a steady-state level of hedonic capital that is not far from the lower bound (represented by a low value of z or a high value of δ). If a further bad, but temporary, life event hits this individual, he or she will use hedonic capital to smooth its effect. The person will initially allow their stock of hedonic capital to fall. But this exposes the individual to a risky situation. If in the next period there is another negative shock, the amount of hedonic capital might drop to the lower bound, with grave consequences. So the individual hoards hedonic capital, meaning that the event is not smoothed as much. The same is true of a person subjected to a sequence of negative shocks: if these shocks are large relative to the size of the stock of hedonic capital, the extent to which they can be smoothed will decline with each shock.

This implies a further result: the extent to which k can be used to smooth life events is an increasing function of its level. To put this in different language, individuals' psychological resilience is dependent on the level of hedonic capital.

For this reason, our model has two implications for such resilience. First, the larger the steady-state level of an individual's well-being, the more resilient human beings will be. People characterized by a high value of z and/or a low value of δ then correspond to what Block and Kremen (1996) describe, without using a formal model, as "ego-resilient". Those with low value of z and/or a high value of δ will be "ego-brittle". Second, a series of positive shocks will, in a sense, make an individual emotionally stronger. He or becomes better able to absorb the effect of a negative

shock. In a cumulative way, positive shocks can buffer a negative one. There is indeed evidence of such buffering in the psychology literature: Fredrickson (2001) writes that "individuals who experienced more positive emotions than others became more resilient to adversity over time".

Need it be the case that happiness goes back, given a long enough span of time, to the original steady-state? That is the extreme 'set point' view (discussed in detail, for example, in Fujita and Diener (2005)). The answer, however, is no. Figure 7 shows how our model can generate a return to a lower permanent level of happiness. Sufficient conditions to obtain this result are that both hedonic capital k and the efficiency parameter z drop at the same time. In this case, two life phenomena occur at time $t=0$, and, although the person recovers much of the original level of happiness, the steady-state level of well-being is permanently lower than 1.00 even as t extends indefinitely beyond period 18 marked on Figure 7.

In principle, as Oswald and Powdthavee (2008) and others have pointed out, decision-makers such as judges in legal compensation cases will sometimes need to take a view on whether happiness is fully mean-reverting (that is, returning literally to the value 1.00). Paradoxically, although the issue is conceptually of fundamental importance to this field, and has been the subject of intense debate in the empirical literature (such as in Easterlin 2003), in many practical cases it may not matter whether there is, say, 90% or exactly 100% adaptation. Imagine, for example, that Time in Figures 1 and 7 is in years. Then, given data in which there is some measurement error, after a decade it may be impossible statistically to detect reliably the difference between the settings of Figure 1 and Figure 7.

Finally, there are four potential roles for income in our model.

First, as we discussed in section 3, increased income can have direct effects on the steady state level of well-being by increasing the steady-state level of hedonic capital through, for example, better health care or risk diversification. Second, an increase of income might raise an individual's sense of status, a component of their hedonic capital. Such effects will be transient in our model, however, as will those of any one-off increase in hedonic capital, even without the peer comparison effects that are

empirically important in evaluation of status. Third, income can help to buffer negative shocks by giving an individual more opportunity to invest in new hedonic capital. Fourth, although we have not included it in our model, a natural possible extension would be to think of a subsistence level of income -- a level below which an individual's ability to employ their own stock of hedonic capital declines. The model provides a reasonably general framework in which to think about the relationship between income and happiness, and each of income's four roles has potentially testable consequences.

7. Generalizing the Framework

For clarity, we have assumed that the only determinants of well-being are the level of hedonic capital and the life-events that strike the human being. To use the terminology of Ormel et al (1999), our social production function contains only a single factor of production. We have alluded to the idea that there are many types of hedonic capital, and that adaptation to life events might involve substituting between types in the way described by Ormel et al (1999). Also, time might be an important factor in the production function. Wilson et al (2005) suggest that time is needed to "make sense" of new events. All these factors could be incorporated into our model by replacing Equation 1 with a production function that distinguishes between different types of capital and allows for other influences on well-being.

What if the ease with which individuals can invest in hedonic capital depends upon the level of hedonic capital? The intuition here would be that it is arguably easier to make friends if one has lots of them. We could include this in our model by adding a production function for investment, showing how both hedonic energy and hedonic capital are needed to produce new hedonic capital.

The framework assumes that investment in hedonic capital and current period well-being are strictly exclusive uses of hedonic energy. Other conceptions are possible. Our model relies on there being some trade-off between current period well-being and investment. But it would be straightforward to extend the model to allow the assumption that investment directly generates some well-being.

With such extensions, the model would be able to make predictions about how the dynamic response of well-being to life events varies with the type of individual.

Another feature of the analysis here is a division of life-events into two types – those with a permanent effect on the level of hedonic capital and those with only a temporary effect. Neither permits permanent effects on the steady-state: neglecting the lower bound, hedonic capital and well-being will always adjust back to their baseline. However, as in Lucas et al (2004), there is reason to believe that some of life's occurrences (for example, marriage) have a permanent effect on well-being, although the size of the permanent consequences may be smaller than the temporary consequences. As captured in Figure 7, this would correspond here to the life event leading to a change in the parameter z on how efficiently hedonic capital is used.

The paper has modelled decision rules that Nature could hard-wire into individuals. What if the opportunities to take the action prescribed by those rules are not available? After some hedonic capital is destroyed, it will be optimal for the individual to build up a new stock to replace that lost. If there are no opportunities to do this (as an extreme case, return to the example of a prisoner in solitary confinement), the level of k , and hence h , will fall to the lower bound.

An interesting asymmetry emerges. Adjustment back to the steady-state after a positive shock to hedonic capital happens mainly because of depreciation, which is independent of investment opportunities. Yet adjustment from a negative shock may require investment in new types of hedonic capital. Hence it will be dependent on opportunities for such investment being available. This potentially goes some way to explaining the observation that, while income does not have large effects on the mean level of well-being, it can buffer the response of well-being to a negative shock (Smith et al (2005)). Income creates opportunities for investment in hedonic capital. That allows an individual to recover from a negative shock, but income will have no significant effect on the response to a positive shock.

8. Further Empirical Implications

We have shown how modelling hedonic capital can provide a conceptual account of the empirical facts of adaptation, the key empirical regularity of the well-being literature. However, models of an endogenous reference level also account for adaptation. In this section we describe four empirical predictions which our model makes but about which reference-level models are silent. These are:

- a. High levels of hedonic capital imply high well-being;
- b. High levels of hedonic capital high psychological resilience i.e. low volatility of well-being;
- c. After a negative shock to the level of hedonic capital, individuals substitute towards activities which rebuild their hedonic capital
- d. Income buffers well-being, and does so more effectively against negative shocks than against positive ones.

Micro data sets contain questions relating to components of hedonic capital such as length of relationship, contact with friends, health, and self-esteem. A number of studies use such data to investigate questions related to our first prediction. A recent example is Aslam and Corrado (2007) which finds that higher levels of a range of stock-like variables imply a higher level of well-being. There is much less work on our second prediction: Clark and Leites (2005) shows that religion can buffer well-being; Graham, Oswald and Powdthavee (2008) use two distinct panel datasets from Germany and Britain to show that high levels of the various components of hedonic capital result in lower volatility of well-being.

Time-use data could be used to examine the third prediction. After a negative shock, do people spend more time on activities which build up their hedonic capital? Do they take up new activities which could provide them with new sources of hedonic capital? These are predictions are testable.

There already exists some evidence to support the framework's fourth prediction (see the results of Smith et al, 2005). This interesting and unusual study, which looks at the buffering effects of income after disability, could be extended in ways suggested by the theory. Richer data set would allow tests for buffering effects in the face of a wider range of shocks. Our model also has implications for how the time-path of

well-being after a shock depends on underlying parameters. Existing data sets are rich enough to allow a start on tests of such predictions.

Another application of our model is as a way of structuring the discussion of life events in well-being research. The model suggests that influences on well-being should be understood either as changes to the parameters of the model (notably δ , the rate at which hedonic capital depreciates and z , the efficiency with which an individual uses their hedonic capital) or as shocks either to the level of hedonic capital or to the flow of psychological resources. The first type of event will have long-run effects on an individual's well-being, the second type only short run effects. Whether a particular type of life event falls into one category or another is a matter for further empirical research, guided by the conceptual framework our model provides.

One example of this would be to throw light on the Easterlin paradox. Some consequences of increasing GDP, such as widely-available health-care, education and insurance might lead to the parameter z increasing between different generations. This would increase the steady-state level of well-being with time. However, if the growth in GDP is accompanied by an increasing rate of depreciation of hedonic capital -- such as higher mobility and the breakdown of traditional communities and roles -- this could offset the increase in z . Then the net movement of well-being would be determined by the relative magnitude of the two effects.

9. Conclusions

This paper studies the dynamics of human well-being and suggests a formal theory of hedonic adaptation. Central to the analysis is a notion we refer to as hedonic capital. This can be viewed as the level of psychological coping resources, or as the stock to which the economist's idea of a flow of 'utility' corresponds.

The model is abstract but the paper's motivation is meant to be practical. Its aim is to fashion an internally consistent framework that can make sense of the observed puzzling resilience and adaptability of mental well-being. Hedonic adaptation occurs when shocks -- becoming disabled or winning the lottery, for example -- gradually wear off. There is now much evidence for phenomena of this kind. Yet adaptive

behavior creates fundamental conceptual problems for the subject of economics. Standard economic models do not fit the facts.

We propose as a concept a person's level of hedonic capital, k . It is defined in the paper as the stock of psychological coping resources available to the individual. Happiness is then akin to a return⁹ on hedonic capital. We argue that the key characteristic of hedonic capital is that it can be drawn down in a crisis (or, correspondingly, built up in better times). In the same general spirit as Rayo and Becker (2007) and Wilson and Gilbert (2005), the paper analyses the nature and roots of habituation. In our framework, however, hedonic capital binds together the present and the future.

The paper provides an analytical model of well-being in which Nature optimally designs human beings' reactions in such a way that bad life-shocks are smoothed by the depletion of hedonic capital. Good life-shocks lead, equivalently, to a happiness response that is damped and mean-reverting. Our framework mimics the key facts of the empirical well-being literature: (i) the existence of a stable mean level of well-being and (ii) adaptation towards that level. Depending on the exact assumptions made, the model leads to full or partial adaptation.

Just as the psychology and economics literatures now examine data on psychological well-being, so, we conjecture, might it become possible to study empirically the level and rate of change of hedonic capital. To do this, it will be necessary to use new measurements, and to ask different kinds of questions than in our existing surveys. Those measurements and questions will explore the nature of mental stocks.

⁹ As explained earlier, this intuitive statement should be tempered by the more precise technical one that hedonic capital in the model is used both for current happiness and to invest in future well-being.

Appendix

A Two Period Model

The paper has relied largely on numerical solution. As a pedagogical aid, it is helpful to give simple analytical results for a two-period version of the model.

Nature designs human beings. In each period, Nature's 'utility' is an increasing function $n(h)$, where h is the happiness of the agent. Assume that $n(\cdot)$ is concave and differentiable. Let there be two periods. Assume there is a discount factor, β . Nature then maximizes a discounted sum of two utility levels. Assume, moreover, that this mini-society has an initial endowment of hedonic energy. Denote it as y . It can be converted into a flow of happiness today or invested to create a flow of extra happiness in the second period. Denote the amount of emotional endowment held over to the second period as k . Assume that happiness in the second period is given by a concave 'production' function $f(k)$. In this 2-period framework, the functional forms and the discounting assumptions are more general than in the multi-period model of the paper.

These assumptions lead to the following. Nature maximizes a concave weighted sum of agents' happiness levels across the present and the future:

$$W = n(h_0) + \beta n(h_1) \quad (A1)$$

where the hedonic energy budget constraint is

$$y = h_0 + k \quad (A2)$$

and happiness in the second period depends solely on the emotional endowment left over from the first period so that

$$h_1 = f(k). \quad (A3)$$

This framework, with just two periods, can produce the appearance of a form of hedonic adaptation (a tendency to a form of mean-reversion). High happiness is followed by low happiness. Low happiness is followed by high happiness. To establish this, note that the structure can be converted into a single-variable maximization problem in which k , the amount of the endowment put into investment, which becomes the level of hedonic capital in the final period, is optimally decided by Nature. The exogenous parameter here is y , which is the size of the starting endowment.

The problem is then that of finding a turning point in the function

$$W = n(y - k) + \beta n(f(k)) \quad (\text{A4})$$

so at an interior maximum

$$\frac{\partial W}{\partial k} = -n'(y - k) + \beta n'(f(k))f'(k) = 0. \quad (\text{A5})$$

This first-order condition defines Nature's rational amount of investment in the future, k , given a starting endowment, y . Let the resulting implicit function be rewritten as $k=k(y)$. As y increases, the optimal amount of k also increases. Its gradient follows from the cross-partial of Nature's maximand in equation (A4). That cross-partial's sign is given by

$$\text{sign} \frac{\partial k}{\partial y} = \text{sign} -n''(y - k) \geq 0 \quad (\text{A6})$$

where, in general, the inequality will hold strictly, so the implied $k(y)$ function is strictly increasing in y .

From the first-order condition, (A5), we know that

$$\beta f'(k) = \frac{n'(h_0)}{n'(h_1)}. \quad (\text{A7})$$

A natural benchmark case is that of equal happiness in each period: $h_1 = h_0$. Hence define a value of y^* , and by monotonicity an implied k^* value, that corresponds to this case and also satisfies equation (A7). It is straightforward to check that y^* is unique. The value of k^* so defined is, from equation (A7), the value of k that solves

$$\beta f'(k^*) - 1 = 0. \quad (\text{A8})$$

There is an associated y^* . At y^* and k^* , happiness in the present h_0 is identical to happiness in the future h_1 . Happiness is steady through time.

To see how a kind of hedonic adaptation then emerges, consider what happens if we move away, either up or down, from the benchmark point.

Case I: The happiness path with an endowment greater than y^* .

Now imagine a society that is richer in emotional endowment. Such a society has a level of $y > y^*$. It therefore has a second-period hedonic capital stock $k > k^*$. But then, by equation (A8) and the first order condition (A5), it follows that

$$\frac{n'(h_0)}{n'(h_1)} \leq 1. \quad (\text{A9})$$

Given strict concavity of the happiness production function, this inequality holds strictly, so that $h_1 > h_0$. In this case, therefore, happiness starts high in the first period and drops in the second.

Case II: The happiness path with an endowment less than y^* .

Alternatively, consider the case where $y < y^*$. Then $k < k^*$. By strict concavity of $f(k)$, we have

$$\beta f'(k) > 1 \quad (\text{A10})$$

and thus

$$\frac{n'(h_0)}{n'(h_1)} \geq 1 \quad (\text{A11})$$

so that the optimal levels of happiness are such that $h_1 < h_0$. In this case, happiness starts low in the first period and rises in the second.

A form of well-being reversal is found in Cases I and II. Good times, or in other words a large endowment of y , act to trigger the appearance of adaptation -- a retrenchment in happiness -- with h_1 below h_0 . In the second period, happiness drops below that in the first period. Bad times have the opposite character. They result in h_0 less than h_1 . In the second period, happiness is higher than in the first period.

This framework does not have the generality of the multi-period model of the paper but it provides an intuitive statement and easy analytical derivation. Below the surface, it is once again concavity and optimization-across-periods, along with the assumption of hedonic capital, that together lead to rational habituation. Although the existence of discounting affects the exact happiness profile through time, it can be checked algebraically that the discount factor itself is not what accounts for the existence of adaptation.
